

Deep Convolutional neural network for Fingerprint Recognition

Elham Tabassi

Xiao Zeng

1. Introduction

Fingerprints are ridge and valley patterns presented on the surface of human fingertips. Fingerprints are used to recognize humans for applications such as verifying an identity claim (*i.e.*, one-to-one search to unlock a smart-phone, for example), or identification (*i.e.*, one-to-many search to find a suspect of a crime, for instance). Typically, to query a fingerprint, the system needs to search and compare the query print with the fingerprints stored in a reference (or enrolled) database. The size of a reference database can be from thousands to hundreds of millions subjects, depending on the application. For example, the Aadhaar project in India has enrolled 111,98,29,743 persons as of February 18, 2017 [?]. As the size of the database grows, the number of comparisons to be made for identification purposes grows, so does the computation time. To mitigate this problem, most fingerprint recognition algorithms first classify a fingerprint into a basic pattern type and then perform fingerprint matching within fingerprints of that type. The major five fingerprint pattern types used today are an extension of the three pattern types (whorl, loop, and Arch) introduced by Henry Faulds (Henry classification system [6]) and Sir Francis Galton [5] in late 19th century. These five pattern types are: arch, left Loop, right Loop, tented arch and whorl, see Fig.1. Because arch and tented arch only accounts for a small portion (around 6%) in human, in some automatic fingerprint identification systems, they combine these two classes into one class. As mentioned above, to manage the computation load, large scale fingerprint identification algorithms employ multi-stage matching whose first step is often filtering based on fingerprint pattern type. As such an accurate fingerprint classification algorithm largely influences the identification accuracy. An error in finger pattern classification will propagate throughout the system, and ultimately result in a recognition error. In this project (paper) we propose an automated fingerprint pattern classification that is not based on feature extraction.

2. Problem statement

The challenge of classifying fingerprint includes: 1) quality of fingerprints, particularly poor quality; 2) the inter-class dissimilarity is small and the intra-class similarity is small, for example, tented arch and loop may look sim-

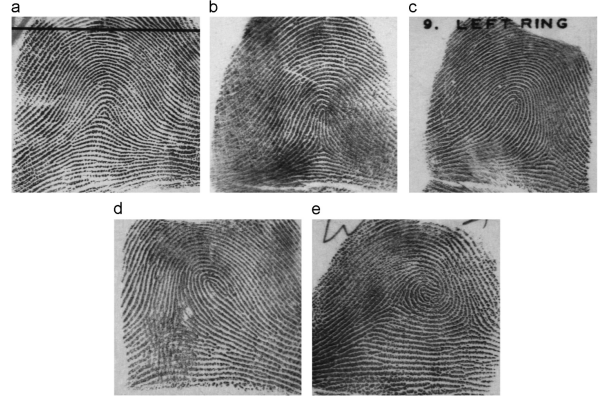

Figure 1. Examples of fingerprint classes: (a) Arch (b) Tented Arch (c) Left Loop (d) Right Loop (e) Whorl. Note that tented and tented arch are similar. [3]

ilar; 3) There are ambiguities in some labels (pattern class). Some fingerprints can be classified into multiple classes, or different classes by different fingerprint experts.

Previous work mostly consist of singularity points (core and delta) detection or extracting features such as ridge and orientation flow, or used human markups (or handcrafted features) as basis for pattern type classification. Therefore, the accuracy of these methods depends on the goodness (or utility) of the selected features and the precision of the feature extraction portion of the algorithms. Both are sensitive to the noise and the variations of the gray-scale level of the input image. Using handcrafted features can improve performance. However, in addition to be burdensome and time consuming, accuracy of handcrafted features cannot be guaranteed due to the existence of noise and poor image quality. Moreover, their repeatability and reproducibility cannot be guaranteed either, due to inter- and intra-examiners variations [12]. Our approach differs from these works in the sense that we aim to use raw images instead of features as input. Convolutional neural network (CNN) has the capability of learning features and it can be directly applied on raw images. CNN also exhibits powerful classification capability in many areas[10][11]. An overview of related work follows. Karu and Jain [8] presented a rule-based classifier based on extracting singular points. Fitz and Green [1] used a Hexagonal Fourier Transform to classify

fingerprints into whorls, loops and arches. Jain *et al.* [7] use a bank of Gabor filters to compute a feature vector (Finger-Code) and then use a K-nearest neighbor classifier and a set of neural networks to classify a feature vector into one of the five fingerprint pattern classes. Cappelli *et al.* [4] partitioned a fingerprint directional image into “homogeneous” connected regions according to the fingerprint topology, resulting in a synthetic representation which is then used as a basis for the classification. Bernard *et al.* [?] used the Kohonen topologic map for fingerprint pattern classification. Kai Cao *et al.* [3] propose to extract fingerprint orientation feature and use a hierarchical classifier for classification. Ruxin Wang *et al.* [13] also use orientation filed as features. By adopting a stacked autoencoder, they achieve 93.1% in four-class classification.

3. Proposed research

In this project, we aim to develop and implement a deep learning algorithm that takes a fingerprint image as an input and classify it into one of the five pattern class types of a) Arch; b) Tented Arch; c) Left Loop; d) Right Loop; or e) Whorl.

3.1. Feature Extraction

We will first apply raw fingerprint images to train a CNN for classification. The outputs of some intermediate layer of CNN will be used as features for possibly a support vector machine classifier. We will consider using automated extracted features (*e.g.*, orientation filed) as inputs for CNN training, with the goal of combining raw images and automated features as input to train CNN.

For CNN architecture, we will first use canonical architecture (such as 5 *convolutional* + 3 *fully-connected* in AlexNet[9]). We will then modify the CNN architecture to improve the performance.

3.2. Classifier

We will consider two classifiers. The first one is the prediction layer of CNN. The values in last layer indicates the predicted probabilities of each class. The second one is support vector machine (SVM whose input features comprise of the CNNs middle or last layers.

3.3. Data Augmentation

To further improve the performance, we will use data augmentation technique to generate more training samples in order to increase the generalization ability of our model. The augmentation methods include rotation, resizing and translation.

4. Dataset

In this project, we will use NIST Special Database 4 [2] for our experiments. Some samples can be seen in Fig.1. The NIST database of fingerprint images contains 2000 8-bit gray scale fingerprint image pairs, totally 4000 images. Each image is 512-by-512 pixels with 32 rows of white space at the bottom and classified using one of the five following classes: Arch, Left and Right Loops, Tented Arch, Whorl. Each of the five classes has 400 pairs. Each of the fingerprint pairs are two completely different rollings of the same fingerprint.
